Preferred running head: Blood flow and performance recovery (36 char/40)

Abstract

Purpose: This study investigated the effect of different limb blood flow levels on cycling performance recovery, blood lactate concentration and heart rate. **Methods:** Thirty-three high-intensity intermittent trained athletes completed two 30 s Wingate anaerobic test sessions: 3 x 30 s Wingate test (WAnT 1-3) and 1 x 30 s Wingate test (WAnT 4), on a cycling ergometer. The two Wingate test sessions (WAnT 1-3 and WAnT 4) were separated by a randomly assigned 24 min recovery intervention selected from among: blood flow restriction, passive rest, placebo stimulation or neuromuscular electrical stimulation-induced blood flow. Calf arterial inflow was measured by venous occlusion plethysmography at regular intervals throughout the recovery period. Performance was measured in terms of peak power and mean power output during the first (WAnT 1) and the fourth (WAnT 4) Wingate test. **Results:** Following the recovery interventions, a *large* ($r = 0.68$ (90% CL 0.42; 0.83)), and *very large* ($r = 0.72$ (90% CL 0.49; 0.86)) positive correlation was observed between the change in calf arterial inflow and the change in mean power and peak power output, respectively. Calf arterial inflow was significantly higher during the neuromuscular electrical stimulation recovery intervention compared to the blood flow restriction, passive rest and placebo stimulation interventions ($P < 0.001$). This corresponds to the only intervention that allowed performance recovery ($P > 0.05$). No recovery effect was linked to heart rate or blood lactate levels. **Conclusions:** For the first time, these data support the existence of a positive correlation between an increase in blood flow and performance recovery between bouts of high-intensity exercise. As a practical consideration, this effect can be obtained by using neuromuscular electrical stimulation-induced blood flow since this passive, simple strategy could be easily applied during short-term recovery.

Key words: limb blood flow level; high-intensity exercise; neuromuscular electrical stimulation; short-term recovery

Introduction

In many sporting situations it is essential to be able to perform and recover rapidly from high-intensity bouts of exercise. As an example, in sprint track cycling, a number of maximal effort performances are necessary in a short period of time. Each bout of high-intensity intermittent exercise results in fuel degradation and metabolic perturbations inducing transitory fatigue which can limit optimal sporting performance¹. Higher levels of fatigue may also predispose athletes to tissue injury or non-functional overreaching. It therefore appears necessary to assist the return to a pre-exercise state for physiological systems in preparation for subsequent exercise. Recovery can be enhanced by applying an appropriate recovery strategy^{2,3}.

To improve high-intensity short-term recovery, many strategies have been suggested. The most frequently proposed mechanism through which strategies may contribute to recovery after high-intensity exercise is by increasing or maintaining local and/or systemic blood flow⁴⁻⁸. Effective recovery strategies enhance blood flow to the recovering muscles, which is assumed to improve oxygen and nutrient delivery, and therefore PCr and glycogen resynthesis⁹, while at the same time transporting lactate and metabolic by-products such as H⁺ ions, Pi, Mg²⁺, and NH₃ away from the active muscles to removal sites and non-exercised muscles¹⁰.

The hemodynamics of arterial circulation are relatively simple to understand; they are dominated by the pumping function of the heart. In contrast, the hemodynamics of venous return in the lower limbs, against gravity, are more complicated and multifactorial, and tend to be dominated by the role played by the contracting calf muscle¹¹. According to some studies, an increase in local and/or systemic blood flow can be achieved through several parameters such as activation of the skeletal muscle pump and release of endothelium-derived relaxing factors which increase venous return and arterial inflow^{12,13}. However, it remains unclear whether greater blood flow immediately after exercise improves short-term recovery

and performance during subsequent high-intensity exercise. Moreover, no study has yet established to what extent the increased blood flow level is sufficient to benefit subsequent performance.

Neuromuscular electrical stimulation (NMES) is a means of increasing blood flow to the muscles through low-frequency stimulation^{14,15}. NMES is used in clinical settings as an effective non-pharmacological means to treat vascular disorders. Involuntary muscle contractions effectively increase lower limb blood flow via the “muscle pump effect” and trigger the release of vasoactive substances¹⁶. Theoretically, this technique could produce some of the benefits expected from active post-exercise recovery¹⁷. NMES could also have the advantage of not impairing the replenishment of muscle PCr and glycogen stores as it limits metabolic demands relative to active recovery¹⁸. Recent scientific evidence indicates that NMES can be considered to be an effective method of enhancing performance recovery compared to alternative methods, in both untrained and athletic populations^{17,19-22}.

As suggested by Broatch, et al.²³ in a recent paper, one major problem with testing recovery modalities is the placebo effect. Indeed, several works focusing on recovery of sporting performance fail to include a placebo situation even though the placebo effect has been extensively described in medicine. The placebo effect influences both sporting performance²⁴ and performance recovery²³. In light of these effects, it is crucial to incorporate a placebo condition in any study.

The aim of the present study was to investigate the influence of different limb blood flow levels, blood flow restriction, passive recovery, placebo protocol and NMES-induced blood flow, applied for the entire duration of the short-term recovery period following a model high-intensity sprint exercise.

Methods

Participants

33 sprinters in cycling and middle-distance runners participated in this study (Table 1). All undertook a minimum of three vigorous exercise sessions per week. After being informed of the experimental procedures and potential risks, all completed the written informed consent. The experiment was conducted in compliance with the Declaration of Helsinki and was approved by the local ethics committee.

Participants were asked to eat as normal (at least 3 h before the test), to stay well hydrated and to abstain from high-intensity physical activities for at least 24 h prior to each session. They also asked to refrain from smoking and consuming drinks containing caffeine and alcohol on the day of each session.

Experimental design

Participants first familiarized with the test protocol to eliminate the practice/learning effects of the protocol. On a subsequent visit, they completed three standard 30 s Wingate anaerobic test (WAnT 1-3), with the purpose of inducing extreme fatigue prior to a randomly assigned 30 min recovery intervention protocol, including 24 min of either: blood flow restriction (BFR), passive recovery (PAS), placebo stimulation (NMES_{Placebo}) or Neuromuscular electrical stimulation-induced blood flow (NMES_{BF+}). After the recovery period, participants completed a single standard 30 s Wingate test (WAnT 4) as the post-intervention exercise session. An overview of the experimental design is presented figure 1.

Wingate test protocols

Participants performed a 5 min warm-up, which consisted of cycling on an electromagnetically braked cycle ergometer (Excalibur sport, Lode BV, Groningen, the Netherlands) at 80 W, at 80 RPM cadence. This also included a 5 s acceleration at the end of

the second minute. Participants then performed 3 x 30 s WAnT in sequence, interspersed by 4 min of cycling at 80 W at 80 RPM. After the recovery period, a single standard 30 s WAnT (WAnT 4), including the 5 min warm-up procedure, was completed as the post-intervention exercise session. For each 30 s WAnT the braking force applied was 7 % body mass for men and 6.5 % for women²⁵. Participants were encouraged to cycle “all-out” at the highest cadence possible for the duration of the 30 s test period and to reach their maximal power as soon as possible. They were instructed to grip the handlebars and to not lift off the saddle while cycling. During each bout the cycle ergometer was controlled via a PC running Lode Wingate software (version 1.0.12, lode BV, Groningen, the Netherlands). Average data for peak power (PPO) and mean power (MPO) output values were recorded over the first (WAnT 1) and the fourth (WAnT 4) Wingate test.

Recovery interventions

Immediately after the first session (WAnT 1-3), participants were randomly assigned to the 30 min recovery intervention protocol, including a 3 min transition from the end of WAnT 1-3 to the setting up of the plethysmograph and skin electrodes or elastic wraps, followed by a 24 min treatment period, then a further 3 min transition period back to the ergometer to complete WAnT 4. For all conditions, including BFR, NMES_{Placebo} and passive conditions, the participants were lead to believe that the proposed recovery modality was beneficial in recovery from high-intensity exercise.

Participants in the NMES-induced blood flow (NMES_{BF+}) condition used a commercially available electrical stimulator of the calf muscles (Veinoplus[®] v.2.1, Ad Rem Technology, Paris, France). The stimulation was applied via two self-adhesive Veinopack 8 x 13 cm surface electrodes (Ad Rem Technology, Paris, France). The electrodes were placed on the medio-central part of the calf, with one electrode for one leg of each participant. It has been

established that this stimulation technology is an effective method of activating the calf muscle pump and enhancing arterial and venous limb blood flow, in healthy individuals and peripheral vascular disease patients^{14,15}. The stimulation pattern and application recommendations are described by Bieuzen, et al.¹⁷ and Cywinski²⁶. A minimal threshold was fixed by the investigators corresponding to a visible contraction of the calf muscles (to act as a muscle pump) with comfortable sensation.

In the NMES_{Placebo} condition, the placebo stimulator was physically identical to the real Veinoplus[®] v.2.1, excepted that the output signal was similar to a weak transcutaneous electrical nerve stimulation and not to the NMES stimulus deliverable by the real Veinoplus[®]. In effect, the placebo stimulator produced a delicate and continuous tingling sensation on the skin, but it was too weak to induce rhythmic and visible contractions of the participant calf muscles.

The blood flow restriction (BFR) was applied with elastic wraps (width, 7 cm; length, 80 cm) that were placed to the upper part of each thigh. They were tightened at a pressure of 90-110 mm Hg interval and maintained at this pressure throughout the 24 min of recovery intervention period. The elastic pressure of 90 - 110 mm Hg interval was selected because the occlusive stimulus at this pressure has been suggested to restrict venous blood flow and cause pooling of blood in capacitance vessels distal to the cuff, ultimately restricting arterial blood flow²⁷. If it is not possible to create a BFR placebo condition, the participants were lead to believe that a compression, with elastic wraps, was beneficial in recovery from high-intensity exercise.

In the passive condition (PAS), participants were placed in the same lying position as for BFR, NMES_{Placebo} and NMES_{BF+} recovery interventions and were instructed to observe passive rest for 24 min.

Measurements

Calf arterial inflow in the left leg was measured by using venous occlusion plethysmography¹⁶. An inflating cuff (SC10D, Hokanson, Bellevue, USA) was placed around the participant's thigh (below the elastic wrap) to occlude venous blood flow and connected to a rapid cuff inflator (E20, Hokanson), which was set above venous, but below arterial pressure (50 mmHg). A suitable strain gauge (Hokanson) was placed around the widest part of the calf (above the NMES electrode) and connected to a plethysmograph (EC6, Hokanson). Participants lay in a supine position with their legs supported 10 cm above heart level to empty the venous system. To exclude the foot circulation, a segmental pressure cuff (TMC7, Hokanson) was placed around the ankle and inflated to 50 mmHg pressure at the same time as the thigh cuff. Data were recorded on a laptop using the NIVP3 arterial inflow studies software (Hokanson). On commencing testing, the cuffs were inflated to 50 mmHg for 5 s at a time. During each 5 s occlusion interval, changes in calf circumference were detected as changes in electrical resistance in the strain gauge. The rate of change was interpolated to represent change in limb volume by using the unit ml per 100 ml/min. Five readings were taken at rest and one reading was at regular interval throughout the 30 min recovery period (i.e. minutes 4, 6, 9, 13, 17, 21, 25 from the end of WAnT 1-3). In the NMES_{BF+} and NMES_{Placebo} conditions, the measures realized during the recovery intervention period needed the electrodes cable unplugging during 5 s but not the power supply allowing the preservation of the device pulse sequence.

Blood lactate and heart rate were considered at rest and at regular interval throughout the 30 min recovery period (i.e. minutes 1, 4, 6, 9, 13, 17, 21, 25 from the end of WAnT 1-3). Blood lactate concentrations from capillary finger samples (20 µl) were collected and analyzed with a Biosen Lactate analyzer (Biosen C-line analyzer, EKF Industrie, Elektronik GmbH,

Barbelen, Germany). Heart rate was recorded every 5 s throughout all experimental protocol (Polar RS400, Polar, Kempele, Finland).

Finally, participants were asked to evaluate the recovery intervention (efficacy: « how recovered do you feel after this recovery intervention? »; well-being: « how did you like this recovery intervention? ») by means of a 10 points visual analogue scale, ranging from “not at all” (0 point) to “very, very much” (10 points)²⁸.

Statistical analyses

We assessed the normality of each variable from a normal probability plot and confirmed the distribution using the Kolmogorov-Smirnov statistic. Homogeneity of variance was assessed with Levene's test. Each of these analyses was performed using SPSS® 20.0 software (SPSS, Chicago, Illinois, USA). Of note, statistical analysis was performed on 31 complete data sets because one participant of the NMES_{BF+} condition did not complete one of its performance bouts and equipment failure occurred during one of the bouts for another participant of the NMES_{Placebo} condition.

A two-way (recovery × time) repeated measures analysis of variance (ANOVA) was used to examine differences in dependent variables (i.e. mean power and peak power output, calf arterial inflow, blood lactate concentration, heart rate and perceptions of recovery) between recovery intervention means at each time point. If a significant main effect was observed, pairwise comparisons were conducted using Bonferonni post-hoc analysis. For these analyses, significance was accepted at $P < 0.05$.

The relationships between the change in performance (mean power and peak power output) and the change in blood flow were assessed by analysis of individual response. For each individual, the difference in response to a given variable was calculated as a percentage of the individual response between the first (WAnT 1) and the fourth (WAnT 4) Wingate test

(i.e., mean power and peak power output) for performance and between the rest, before the testing session, and the recovery intervention period (i.e. 24 min) for calf arterial inflow. A Pearson’s product-moment correlation analysis was used to examine the relationship between the change in performance, mean or peak power, and the change in blood flow. The following criteria were adopted to interpret the magnitude of correlation (r) between test measures: ≤ 0.1 , *trivial*; $> 0.1-0.3$, *small*; $> 0.3-0.5$, *moderate*; $> 0.5-0.7$, *large*; $> 0.7-0.9$, *very large*; $> 0.9-1$, *almost perfect*²⁹. If the confidence limits overlapped zero, the outcome was considered unclear. Data are presented as means \pm SD, unless otherwise stated.

Results

Calf arterial inflow

The variation of calf arterial inflow expressed as a percentage of the pre intervention measurement is presented in Table 2. Analysis of variance revealed a significant effect for recovery type ($F_{3,29} = 52.86$, $P < 0.001$), time effect ($F_{2,58} = 9.74$, $P < 0.001$) and recovery type x time interaction ($F_{6,58} = 2.47$, $P = 0.03$). Post-hoc analysis indicated that calf arterial inflow was significantly higher during the NMES_{BF+} recovery intervention compared to the BFR, PAS and NMES_{Placebo} recovery interventions ($P < 0.001$). Calf arterial inflow was significantly lower during the BFR recovery intervention compared to the PAS and NMES_{Placebo} recovery interventions ($P < 0.001$). Post-hoc analysis indicated that calf arterial inflow was significantly decreased at the end of of the recovery intervention period (21-25 min) compared to the start of this period (4-9 min) only in the NMES_{BF+} recovery intervention ($P < 0.001$).

Performance

Table 2 details the sum of the total work measured during the first Wingate anaerobic test session (WAnT 1-3), the mean power (MPO) and peak power (PPO) output values of the

first (WAnT 1) and the fourth (WAnT 4) Wingate test. The sum of the total work during WAnT 1-3 was not different between groups ($F_{3,27} = 0.007$, $P = 0.99$). Analysis of variance of the mean power (MPO) and peak power (PPO) output values revealed a significant effect for time ($F_{1,27} = 107.31$, $P < 0.001$) and a significant recovery type x time interaction ($F_{3,27} = 10.64$, $P < 0.001$). However, there was no recovery effect ($F_{3,27} = 10.64$, $P = 0.40$). Post-hoc analysis indicated that PPO and MPO output values were impaired at WAnT 4 compared with WAnT 1 when BFR ($P < 0.001$), PAS ($P < 0.001$) and NMES_{Placebo} ($P < 0.05$) recovery interventions were used.

Relationship between calf arterial inflow and subsequent exercise performance

The relationships between the change in calf arterial inflow (between rest and 24 min recovery intervention period) and the change in mean power (A) and peak power (B) output values (between WAnT 1 and WAnT 4) are presented in figure 2. Pearson’s product-moment correlation analysis revealed a *large* ($r = 0.68$ (90% CL 0.42; 0.83)), and a *very large* ($r = 0.72$ (90% CL 0.49; 0.86)) correlation between the change in calf arterial inflow and the change in mean power and peak power output, respectively.

Blood lactate and heart rate

Data for blood lactate concentration and heart rate are presented in figure 3. Analysis of variance revealed a significant time effect (blood lactate, $F_{7,21} = 616.26$, $P < 0.001$ and heart rate, $F_{7,21} = 118.34$, $P < 0.001$) but no recovery effect ($F_{3,27} = 1.02$, $P = 0.40$ and $F_{3,27} = 0.25$, $P = 0.86$, respectively) and no recovery type x time interaction ($F_{7,21} = 0.99$, $P = 0.48$ and $F_{7,21} = 1.09$, $P = 0.37$, respectively).

Perceived recovery

Table 3 details the mean recovery perceptions at the end of the recovery intervention period. No significant difference between BFR, PAS, NMES_{Placebo} and NMES_{BF+} recovery

interventions was observed, based on the scores awarded by participants on the two visual analogue scales (efficacy and well-being) ($P > 0.05$).

Discussion

To our knowledge, this is the first study to compare the effects of applying different limb blood flow levels during recovery after exhausting exercise. From our data, NMES_{BF+}, inducing a $\sim 243 \% \pm 76 \%$ calf arterial inflow increase between rest and recovery intervention period, is of greater benefit to repeat performance than interventions involving blood flow restriction (BFR), passive recovery (PAS) or placebo stimulation (NMES_{Placebo}). This outcome is supported by several recent studies demonstrating better performance following NMES protocols^{17,19-22}. However, methodological aspects of NMES can significantly alter its impact on performance. The aspects known to be influential include the stimulation intensity selected, the frequency modulations and the location to which stimulation is applied. In addition, the efficacy of this recovery strategy also depends on the duration of stimulation during each phase, the total treatment time relative to the total recovery time, and the profile of the performance test. None of these appear to have been examined previously in a systematic manner. Moreover, even if a minimal threshold was set by investigators, corresponding to a visible contraction of the calf muscles with comfortable sensation, there appears to be a certain degree of individual variability in sensitivity to blood flow response with NMES_{BF+} (values ranging from $161 \% \pm 49 \%$ to $386 \% \pm 77 \%$ calf arterial inflow increase for the variation between rest and recovery intervention period). As an example, Griffin et al. (2010) in their study reported gender as a clinical factor affecting efficacy of NMES_{BF+} on leg venous flow, in healthy individuals. Indeed, male gender was associated with a higher peak systolic velocities and higher values of ejected total volume per minute, in the popliteal veins. Therefore, further research is needed to identify the most appropriate blood flow stimulation level for performance recovery, depending

on recovery period and exercise modes. This could elucidate the relative importance of the blood flow modulation in improving exercise performance.

Interestingly, a $66 \% \pm 57 \%$ and $71 \% \pm 37 \%$ calf arterial inflow increase during recovery intervention period, compared to baseline values, was noted with the passive and placebo protocols, respectively. This increase in blood flow is a physiological response reflecting exercise-induced reactive hyperemia. Indeed, an enormous increase in blood flow to the skeletal muscle is necessary during exercise to meet the 20 to 50 fold increase in oxygen and substrate consumption required to support the significant increase in metabolic activity within the active muscles⁹.

Notwithstanding limb blood flow level differences induced by the four recovery interventions, no significant difference was noted between BFR, PAS, NMES_{Placebo} and NMES_{BF+} on heart rate, during the 24 min intervention period. In one hand, we suggest that the first exercise session, corresponding to a very exhaustive exercise, could have induced an important cardiac demand, needing a long recovery period to return to baseline. Indeed, Malone, et al.⁸ in their study have realized the exact same exercise-induced fatigue protocol (3 x 30 WAnT). They found similar results regarding heart rate during a 30 min recovery period of passive or NMES induced-blood flow recovery intervention. In a second hand and based of the Franck-Starling law of the heart, we hypothesize that the four recovery interventions could have influenced preload, stroke volume and cardiac output, without having an influence on heart rate. Finally, as heart rate is a parameter with very individual response regard rest and exercise, a parallel study could have made differences greater between recovery interventions. Further investigation is needed to clarify the physiological impact of the limb blood flow modulation on the cardiac parameters.

When considering NMES_{BF+} as an aid to recovery between repeated high-intensity exercise sessions, several effects are expected which could potentially explain the improvement

in performance recovery observed with the blood flow stimulation protocol used here. The first effect is an acceleration of the removal of metabolic by-products from the muscle through an increase in or maintenance of local and/or systemic blood flow. Maintaining adequate blood flow to the recovering muscles will allow clearance of the accumulated lactic acid and other metabolic by-products which could otherwise adversely affect muscle function³⁰. By maintaining or increasing blood flow, lactate can be redistributed to alternative sites such as the liver, heart and non-exercised muscles where it can be used as fuel or converted back to glucose and returned to the working muscles^{31,32}. However, we found no significant differences in blood lactate concentrations in the conditions tested (BFR, PAS, NMES_{Placebo} and NMES_{BF+}) at any time point during the 30 min recovery period. This observation contradicts reports in other studies where blood lactate was found to be more effectively cleared when NMES was applied during recovery^{17,31,32}. In particular, NMES was reported to improve the clearance of blood lactate following 200 yards swimming³² or exhausting climbing exercise³¹, although these studies did not test for an associated effect on performance recovery. The lack of difference in blood lactate levels between NMES_{BF+} and other recoveries in the present study could be explained by the location to which NMES was applied. To induce a systemic approach, the NMES electrodes were applied to the calf muscles in our study, since these muscles generate most of the venous return. The capacity of NMES to speed blood lactate removal compared with passive rest reported elsewhere could be explained primarily by the increase of lactate release from the exercising muscles. Indeed, Bangsbo, et al.³³ demonstrated that lactate uptake by inactive muscles is higher when local blood flow is increased by active recovery. Thus, applying a systemic treatment may decrease the effectiveness with which lactate is released from the active muscle during exercise. Authors^{17,31,32} tend to confirm this suggestion, as the muscles exposed to NMES during their recovery interventions tended to be those mainly mobilized during the exercise performed. Since the quadriceps were heavily

involved in this exercise protocol, applying electrodes on this large muscle group could have improved lactate kinetics during recovery. However, the data of this present study do not allow to determine more precisely the mechanism by which lactate is removed, depending on the limb blood flow level. Further investigations are needed.

The second effect expected from the increase in blood flow induced by NMES during recovery can be partly explained by the muscle pump theory. Indeed, the muscular contraction reduces venous pressure within the active muscle, thus increasing the arteriovenous pressure gradient. One-way flow is ensured in the veins via one-way valves; the enhanced arteriovenous pressure gradient therefore results in an increase in arterial blood reaching the skeletal muscles¹². Because of this increase in arterial blood flow, NMES could increase oxygen supply to the exercised muscles³² and glucose uptake by the muscle cells³⁴. For more than one hour after intense exercise, both pulmonary and muscle oxygen uptake can remain above resting levels³⁵. This increase in oxygen demand is related to reloading of myoglobin and hemoglobin, resynthesis of ATP, PCr and, to a lesser extent, resynthesis of glycogen from lactate and other glycolytic intermediates. These findings support an important role for aerobic metabolism during repeated high-intensity exercises. Moreover, elevated blood flow during recovery increases glucose delivery to the muscles and its uptake, thus promoting glycogen synthesis³⁶. Indeed, Bangsbo, et al.³³ attributed a large percentage of muscle glycogen resynthesis to glucose uptake after short-term, high-intensity exercise. Furthermore, high-intensity exercise promotes maintenance of a high glucose level as a substrate for glycogen resynthesis, particularly in the early phase of post-exercise recovery³⁷.

Finally, NMES_{BF+} recovery intervention is thought to improve perceived recovery, this would explain how high-intensity performance is restored during a short-term recovery period^{28,38,39}. No other studies have fully explored the psychological effects of using NMES on performance parameters. Thus, it is not known whether information relating to techniques used

during recovery could affect an athlete's pacing strategy in high-intensity short-duration exercise and/or whether pacing could be indicated before the exercise due to an effect on perceived recovery. The results presented in this paper, reporting no placebo effect on either performance recovery or perceived recovery, tend to indicate that the effects of NMES are not purely due to a placebo effect. These findings suggest that the physiological role of NMES-induced blood flow in recovery could be greater than the hypothesized psychological role.

Conclusions and practical applications

The novel finding in the present study is the demonstration of an effective, positive correlation between an increase in limb blood flow and performance recovery between bouts of high-intensity exercise. In comparison to traditional active recovery, this strategy presents the benefit to potentially preserve the organism of a possible energy and thermal overload, compromising the return to homeostasis. At the same time, this simple method can be easily included in a recovery routine, in sporting events inducing short recovery periods, during half-time in team sports and for sports with successive rounds. In particular, NMES-induced blood flow can be mixed with other recovery modalities, such as hydration and nutritional strategies, in the first moments following exercise when the time available for recovery is crucial but limited. Additional work utilizing NMES-induced blood flow during shorter or longer recovery periods and other exercise modes could elucidate the relative importance of the blood flow modulation in improving exercise performance.

“Relationship Between Blood Flow and Performance Recovery: A Randomized, Placebo-Controlled Study”

by Borne R, Hausswirth C, Bieuzen F

International Journal of Sports Physiology and Performance

© 2016 Human Kinetics, Inc.

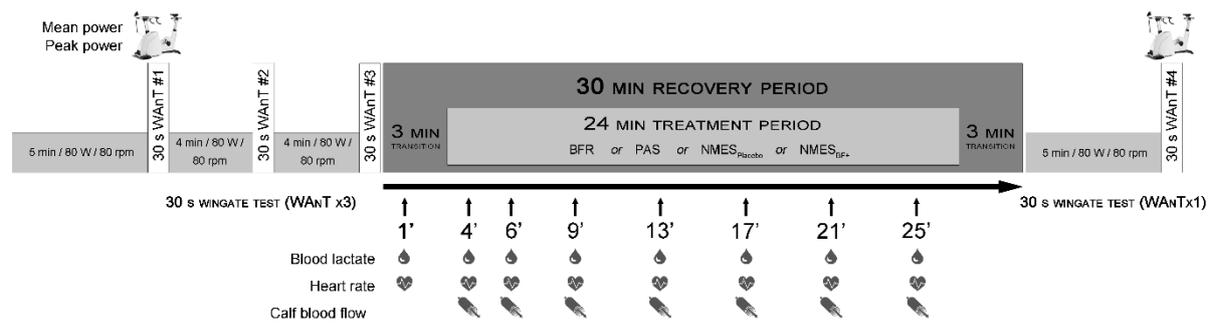

Figure 1. Study design. WAnT, Wingate test; BFR, Blood flow restriction; PAS, passive; NMES_{Placebo}, placebo; NMES_{BF+}, neuromuscular electrostimulation-induced blood flow.

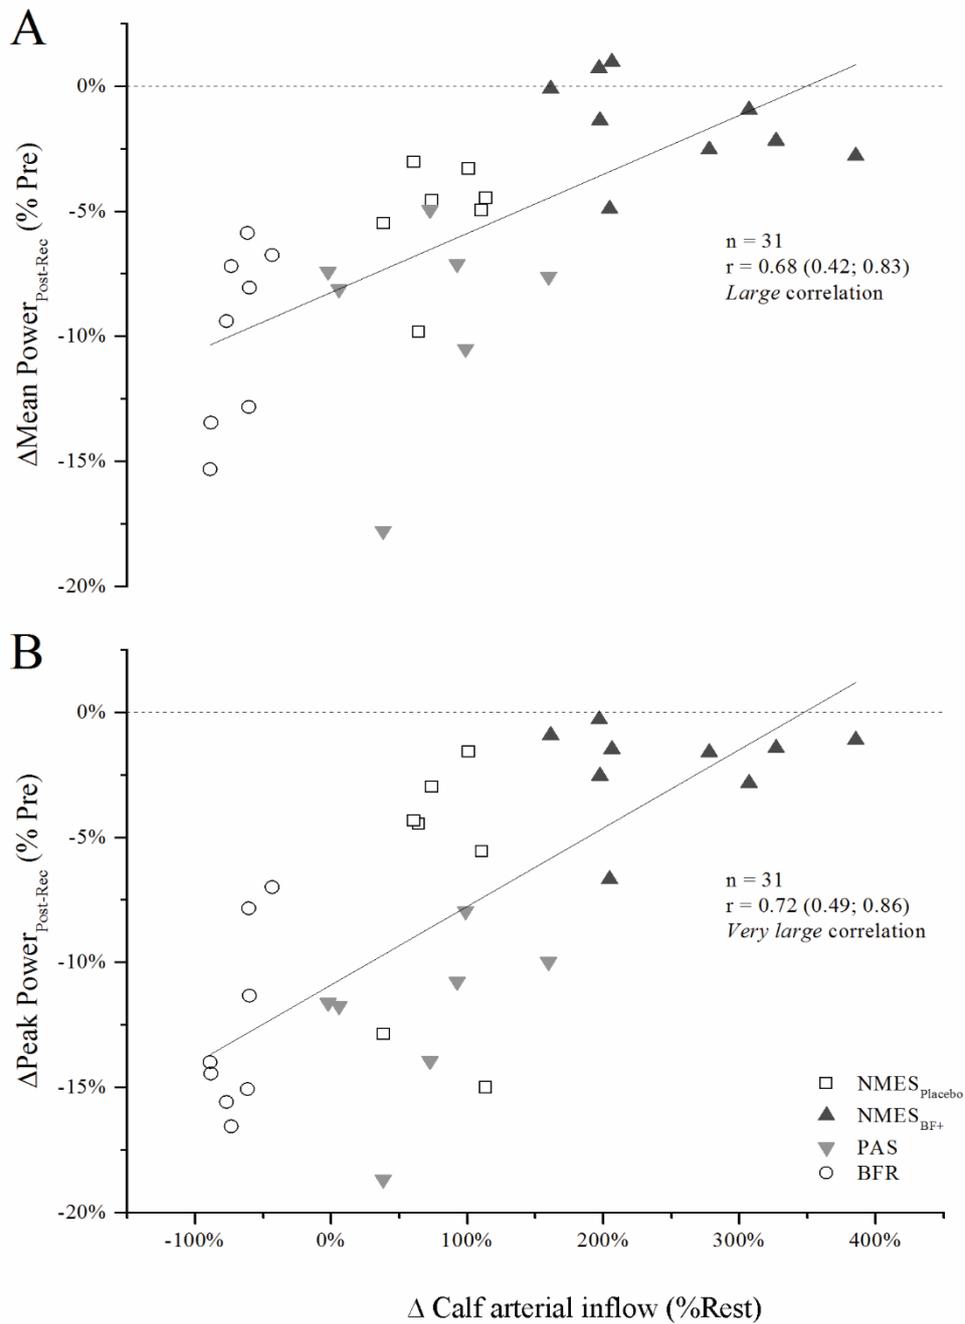

Figure 2. Relationship between the change in Mean Power_{Post-Rec} (A) and Peak Power_{Post-Rec} (B) output and the change in calf arterial inflow following either blood flow restriction (BFR, ○), passive (PAS, ▼), placebo (NMES_{Placebo}, □) and neuromuscular electrostimulation-induced blood flow (NMES_{BF+}, ▲) recovery interventions.

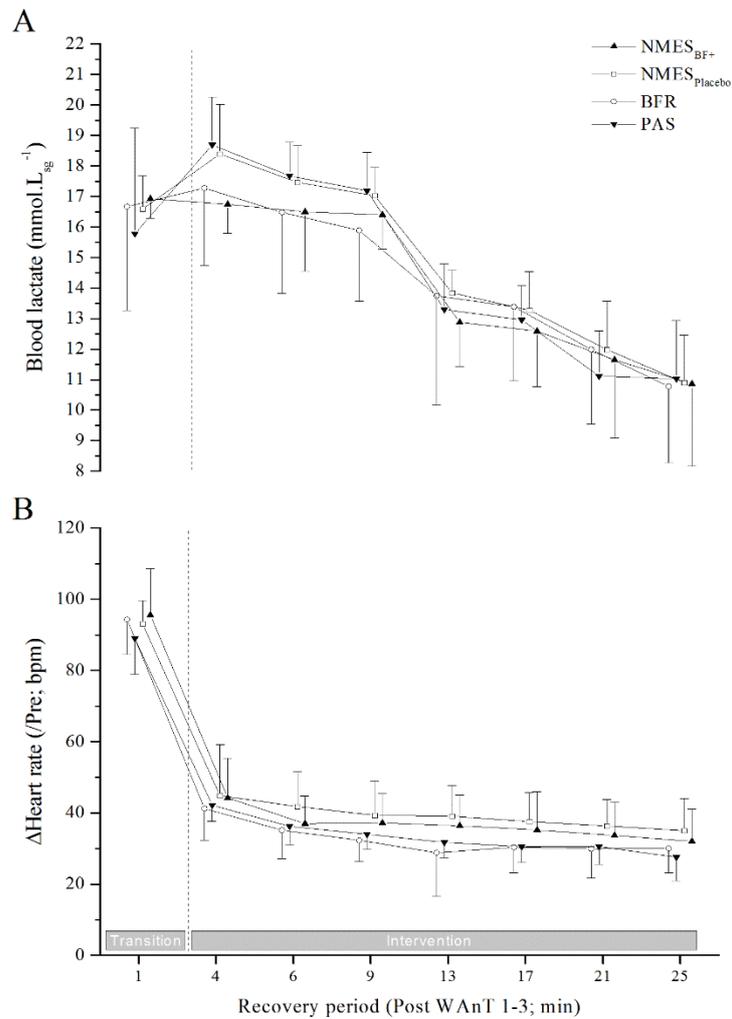

Figure 3. Blood lactate concentration (A) and changes in heart rate from rest (B) (mean \pm SD) during blood flow restriction (BFR, \circ), passive (PAS, \blacktriangledown), placebo (NMES_{Placebo}, \square) and neuromuscular electrostimulation-induced blood flow (NMES_{BF+}, \blacktriangle) interventions throughout the recovery period. No significant differences between the four recovery intervention protocols.

Table 1. Participant physical characteristics (mean \pm SD).

| | NMES_{BF+} | NMES_{Placebo} | BFR | PAS |
|----------------------------|---------------------------|-------------------------------|------------------|------------------|
| Number | n = 10 [♂ = 8, ♀ = 2] | n = 8 [♂ = 6, ♀ = 2] | n = 8 [♂ = 8] | n = 7 [♂ = 7] |
| Age (years) | 30 \pm 5 | 23 \pm 4 | 30 \pm 7 | 24 \pm 3 |
| Height (cm) | 173 \pm 8 | 173 \pm 5 | 177 \pm 6 | 181 \pm 3 |
| Body mass (kg) | 69 \pm 12 | 71 \pm 15 | 70 \pm 8 | 74 \pm 5 |
| Body fat (6 sites) (%) | 9.9 \pm 2.4 | 9.8 \pm 2.3 | 9.2 \pm 2.1 | 9.7 \pm 2.5 |
| Training hour per week (h) | 9 \pm 3 | 7 \pm 3 | 9 \pm 3 | 8 \pm 1 |

Table 2. Sum of the total work measured during the first Wingate anaerobic test session (WAnT 1-3). Mean power (MPO) and peak power (PPO) values of the first (WAnT 1) and the fourth (WAnT 4) Wingate test and variation of calf arterial inflow between rest and recovery intervention protocol following neuromuscular electrostimulation-induced blood flow (NMES_{BF+}), placebo (NMES_{Placebo}), blood flow restriction (BFR) and passive recovery (PAS) interventions. Values are expressed in mean ± SD.

| | | NMES _{BF+} [§] | NMES _{Placebo} | BFR [§] | PAS |
|--|------------|----------------------------------|-------------------------|------------------|-------------|
| Total Work (KJ; 10³) | ∑ WAnT 1-3 | 51.7 ± 13.5 | 51.3 ± 7.8 | 51.6 ± 2.2 | 52.0 ± 12.4 |
| PPO (W) | WAnT 1 | 793 ± 140 | 822 ± 201 | 857 ± 133 | 843 ± 59 |
| | WAnT 4 | 774 ± 125 | 759 ± 139 [#] | 746 ± 98* | 741 ± 64* |
| MPO (W) | WAnT 1 | 687 ± 118 | 630 ± 109 | 660 ± 68 | 698 ± 61 |
| | WAnT 4 | 676 ± 106 | 598 ± 106 [#] | 594 ± 52* | 634 ± 60* |
| BF (% Pre) | 4-9 min | 249 ± 86 | 75 ± 52 | -72 ± 17 | 75 ± 52 |
| | 13-17 min | 230 ± 73 | 68 ± 41 | -68 ± 15 | 65 ± 66 |
| | 21-25 min | 195 ± 71 [#] | 52 ± 39 | -64 ± 18 | 39 ± 28 |

*, Represents a significant difference from WAnT 1 (p < 0.001); #, represents a significant difference from WAnT 1 (p < 0.05).

§, Represent a significant difference in calf arterial inflow from other interventions at each time point (P < 0.001).

#, Represent a significant difference in calf arterial inflow from the 4-9 min measurement period (P < 0.001).

Table 3. Perceptions of recovery (efficacy and well being) responses (mean \pm SD) following neuromuscular electrostimulation-induced blood flow (NMES_{BF+}), placebo (NMES_{Placebo}), blood flow restriction (BFR) and passive recovery (PAS) interventions. No significant differences between the four recovery intervention protocols.

| | NMES _{BF+} | NMES _{Placebo} | BFR | PAS |
|---------------------|---------------------|-------------------------|---------------|---------------|
| Recovery efficacy | 7.2 \pm 1.9 | 5.8 \pm 1.9 | 5.7 \pm 1.4 | 5.4 \pm 2.4 |
| Recovery well-being | 7.3 \pm 2.0 | 5.7 \pm 3.5 | 5.9 \pm 2.5 | 5.4 \pm 2.6 |
